Operating Systems Principles

Recap of Some Basics

CPU Management (Processes)

Recap of Basics

- Key to OS acting as a control program and a resource controller are following CPU/memory facilities
 - #1: Multiple CPU modes and privileged instructions
 - #2: The notion of traps (part of CPU design)
 - Related concepts: Interrupts and signals
 - #3: Memory address translation and protection facilities (hardware called memory controller)
 - Related: Translation Lookaside Buffer (TLB)

Memory Protection and Translation

- •Key Idea #3: Virtual vs. Physical addresses
- •Multiple processes and the OS can generate the same virtual address
- •Need to translate to different physical addresses for protection
- •Done by a piece of hardware called the memory controller
- •Where are address translations kept?

Memory Protection and Translation

- Address translations kept in memory in data structures called page tables
- •A subset of translations stored in a fast on-CPU cache called Translation Lookaside Buffer (TLB)
- •Memory Controller, TLB, and OS cooperate to keep correct translations

CPU Management

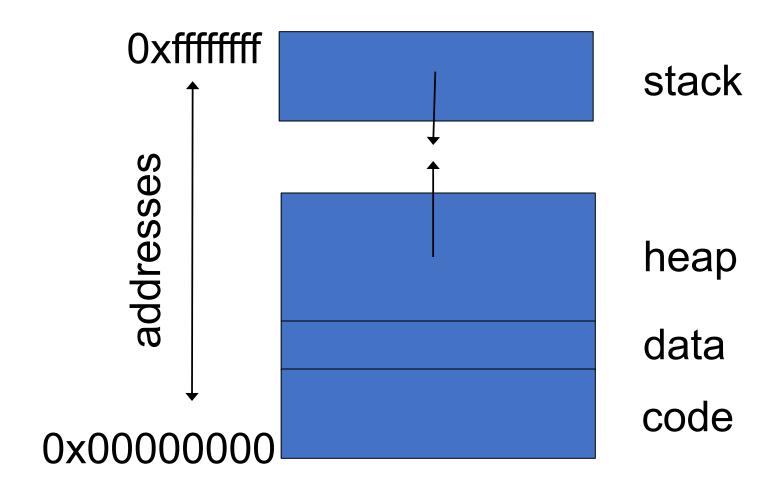

CPU Mgmt: What we will study

- What is the OS's role in sharing CPU among user programs?
- What does a user program expect from the computer and how does the OS help provide this?

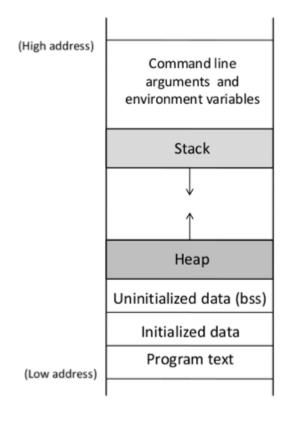

Process

- Roughly, a running program
 - Check out info offered by commands like top, /proc, etc.
- A closer look:

Process Address Space

Program Memory Layout

Function Stack Layout

```
Stack
                                                                               (High address)
void f(int a, int b)
                                                                                           grows
                                                             Value of b
                                     (1) Arguments -
     int x,y ;
                                                             Value of a
                                                           Return Address
                                                   (2)
                                                       Previous Frame Pointer
                                                                                 — (5) ebp
                                                             Value of x
                                  (4) Local variables -
                                                             Value of y
                                                                               (Low address)
```

Function Stack Layout

```
Stack
void f(int a, int b)
                                   grows
                                                                            (High address)
  int x;
                                          main()
                                          stack
                                          frame
void main()
                                                          Value of b: 2
                                                          Value of a: 1
  f(1,2);
                                          f()
                                                                                 Points to printf()
  printf("hello world")
                                                         Return Address
                                          stack
                                                                                 in main()
                                          frame
                                                      Previous Frame Pointer
                                                           Value of x
                                                                            (Low address)
```
